September 18, 2025

Abstract

We explore how CEO ownership affects productivity in small and large firms. We use administrative panel data on the universe of limited liability firms in Finland and exploit plausibly exogenous variations to CEO ownership induced by shocks to the CEO spouse's health. We document a substantial increase in productivity when the CEO obtains majority ownership or when the majority owner becomes the CEO. While typical samples focus on large public firms, we show that our effects are stronger in medium-sized private firms. Consistently with the quiet life hypothesis, we show that increased ownership boosts CEO's effort at work.

Keywords: CEO ownership, firm productivity, SME.

JEL codes: G30, M12, D24, E23, L25.

*We thank various seminar participants and in particular Marianne Bertrand, Matteo Bobba, Catherine Casamatta, Pierre Dubois, Viktor Fedaseyev, Egle Karmaziene, Matti Keloharju, Timo Korkeamäki, Ulf von Lilienfeld-Toal, Sophie Moinas, Sébastien Pouget, Silvia Rossetto, Angelo Secchi, Tuomas Takalo for very useful conversations. Milo Bianchi acknowledges funding from ANR (ANR-17-EURE-0010 grant). We have no material interest that relates to the research described in the paper.

1 Introduction

The separation between ownership and control, and its consequences in terms of firms' investment and financing decisions, have been at the heart of much of the corporate finance literature, starting at least with Berle and Means (1932) and Jensen and Meckling (1976). While the early literature has mostly focused on firms with widely dispersed shareholders, the typical firm today tends to be much more closely held (Aminadav and Papaioannou (2020), Medina, de la Cruz and Tang (2022)). Whether the separation between ownership and control has significant effects as ownership structures become more concentrated, and how much these effects may extend beyond typical samples of large and listed firms, remain open questions.

These questions appear of first-order importance. The scope for inefficiencies may be sizeable also in privately owned small and medium-sized enterprises (SMEs), which for example face less stringent regulatory constraints and weaker outside markets for corporate control than large public firms. At the same time, often because of data limitations, it is typically hard to assess how efficiently these firms allocate their resources.¹ This is relevant also from a policy perspective, given that many countries devote sizeable resources to the development of SMEs, with targeted policies including easier access to credit, advantageous tax treatments, lighter regulatory burdens.²

We investigate the relation between CEO ownership and firm productivity by exploiting administrative panel data covering the universe of limited liability firms in Finland. We have access to a large set of information on the firm's balance sheet, on its employees and, importantly, on its ownership structure in terms of holdings and identity of the ultimate shareholders. This offers the opportunity to investigate the effects of ownership and control in the entire population of firms, and to uncover whether CEO ownership matters even outside typical samples of listed firms and even in firms with highly concentrated ownership structure. The exceptional richness of these data also allows to address in a novel way some issues related to the endogeneity of ownership and control, as we detail below.

¹See e.g. Ayyagari, Demircuc-Kunt and Maksimovic (2011), Li and Rama (2015), Martin, Nataraj and Harrison (2017) for recent discussions.

²See for example the *Small Business Jobs Act* in the US or the *SME Strategy for a sustainable and digital Europe* in the EU. SME-specific policies have also been a common response to the Covid crisis (see e.g. the OECD's report on *Policy Responses to Coronavirus*, July 2020).

Our setting is also interesting in terms of external validity. Finland as a country scores very highly in terms of corporate governance; for example, it was ranked first in the world by the World Bank’s Corporate Governance Index (Kaufmann (2004)). As we will see, we estimate large effects of CEO ownership on firm productivity, and this is remarkable especially in a setting in which, under this perspective, inefficiencies should be minimal.

The logic of our empirical exercise is straightforward. We design a procedure (explained below) to identify the CEO among the firm’s employees, and assume that the firm’s operations are under the *effective* control of the CEO.³ In our baseline analysis, we say that there is no separation between ownership and control when the CEO is also the majority shareholder (in robustness checks, we consider other thresholds of CEO ownership). We then compare firm productivity, defined in our baseline specification as value added per worker, when ownership and control are in the same hands relative to when they are separated.

In our empirical analysis, we develop two complementary approaches. First, we consider fixed-effects specifications in which we exploit variations in CEO ownership over time. Second, we build on some key features of our data to employ a novel IV strategy based on health shocks.

We start with fixed-effects regressions in which we exploit variations in CEO ownership within the same firm with the same CEO. That is, we compare firm productivity within the same firm-CEO pair in years in which the CEO is the majority owner vs. years in which ownership and controls are separated. In addition to any common time trend, this specification allows to capture any time-invariant characteristic of the firm, of the CEO, and of the firm-CEO match. In a similar way, we also define pairs in terms of a firm and its largest owner, and estimate changes in firm productivity, within the same firm-owner pair, in years in which the largest owner is the CEO vs. years in which the two are separated. These specifications consistently show that firm productivity is significantly larger when the CEO is also the majority owner. In a given firm-CEO pair, for example, having the CEO owner is associated with an increase of 1,000 euros in labor productivity, which corresponds to a 1.9% increase. The effect is large, as compared for example to an average productivity growth in our sample of 0.7%. We show that the effect is driven by changes in CEO ownership and not by any change in ownership structure nor by any CEO change.

³Using the terminology in Burkart, Gromb and Panunzi (1997), we say that the CEO has effective control, irrespective of whether or not she has formal control in the firm. Aghion and Tirole (1997) make a similar distinction between formal and real authority.

A causal interpretation of these results requires that unobserved heterogeneity is time invariant within a given firm-CEO or a given firm-owner pair. This assumption may be violated if unobserved pair-specific shocks induce a change in CEO ownership and at the same time affect future firm productivity. For example, the CEO may decide to change her ownership shares in response to her private information about the firm’s prospects (Louis and White (2007), Inderst and Mueller (2010)). An ideal setting to address these concerns would be one in which the CEO has majority ownership and for exogenous reasons she has to step down as CEO while at the same time keeping her shares (this would induce a separation between ownership and control) or, symmetrically, a situation in which the CEO is not the owner and, as result of an exogenous shock, she gets replaced by the owner (this would bring together ownership and control). Our IV procedure attempts to mimic such ideal situations by exploiting shocks to CEO ownership induced by worsened health conditions of the CEO or of the CEO spouse. These shocks may induce the CEO to leave, without necessarily affecting her ownership shares. Depending on whether the CEO is also the owner, these shocks may induce a positive or a negative change to our CEO-owner treatment variable.

We obtain for each CEO the amount of health benefits paid out from the Finnish health insurance scheme, where increased health benefits are associated to worsened health conditions. In a somewhat more extreme way, CEO’s health shocks have been exploited in the literature using CEO death (e.g. Johnson, Magee, Nagarajan and Newman (1985), Jenter, Matveyev and Roth (2018), Becker and Hvide (2022)). Most closely related to our study, Bennedsen, Pérez-González and Wolfenzon (2020) show on the universe of limited liability firms in Denmark that firm’s profitability is significantly affected by the CEO’s absence due to hospitalization. While our instrument is similar, our focus is complementary. Bennedsen et al. (2020) show that CEO hospitalizations matter even when these are not associated to managerial turnover. In our case, we are interested in using worsened health conditions as an instrument for managerial turnover, which as mentioned above may be associated to a positive or a negative shock to our treatment.

When exploiting CEO’s health shocks, we can allow for direct contemporaneous effects of CEO’s health on firm productivity as well as for the possibility that past firm performance affects current CEO’s health. We need however that current CEO’s health is not directly associated to future firm productivity. In order to relax this assumption, one would like to exploit shocks that induce the CEO to resign but are orthogonal to any dynamics occurring within the firm. A key aspect of our data is that they allow us to recover the amount of health benefits paid out

to the CEO spouse, and so consider shocks to the CEO spouse’s health. In order to make the test even sharper, we restrict to CEO spouses who are not working in the firm and have no direct effect on the firm operations.

The IV estimates confirm our results, showing that firm productivity is significantly larger when ownership and control are in the same hands. Estimated coefficients are similar across specifications, and in fact larger than the OLS counterpart. Having the CEO owner induces an increase of about 1,500 euros in labor productivity, which corresponds to a 2.8% increase. This is confirmed in various robustness checks.

The validity of our instruments requires that their effect is only mediated by a change in our treatment, i.e., by episodes in which the main owner becomes or stops being the CEO, and not by any change in the CEO. This assumption can be questioned in light of the evidence (reviewed below) that CEO’s departures may directly affect firm value. We perform a series of placebo regressions in which health shocks are used to induce changes in CEOs that are not associated to changes in our treatment. While indeed our instruments are strongly related to CEO departures, our effects are not driven simply by CEO turnover. Rather, our estimated changes in firm productivity are driven by CEO changes that induce a change in our CEO-owner treatment.

A key value added of our investigation is that we can compare our results to estimates obtained in typical samples of large or listed firms. We start by replicating some existing results showing that in listed firms the effect of CEO ownership on productivity is inverted U-shaped, and in fact overall it is negative. While these patterns are confirmed in our data when restricting to listed firms, we show that the effects are significantly different outside the sample of listed firms. CEO ownership has stronger effects on productivity in medium-sized private firms, those with 51-250 employees. As we discuss below, this result does not seem an artifact of our statistical tests; rather, it suggests that medium-sized private firms can be more exposed to inefficiencies. As argued in Bitler, Moskowitz and Vissing-Jørgensen (2005), managers in these firms may have more discretionary power and be harder to monitor than in very small firms; at the same time, as mentioned, they may be subject to weaker regulation or outside pressure. These results are confirmed when employing the same IV specifications described above, interacting our CEO-owner treatment indicator with firm size. They highlight the importance of exploring the effects of CEO ownership outside typical samples. The estimates one gets in our broader sample are richer, and they suggest that inefficiencies may be particularly severe in firms that, due to data limitations, are often excluded

from corporate governance studies.

We then investigate some possible mechanisms behind our effects, in connection with the literature on family firms (reviewed below) and more generally on agency costs. An important caveat is that our data do not allow to directly identify family firms nor to provide direct measures of agency conflicts. Some key variables, e.g. those requiring an estimate of the firm's asset value, may be measured with noise, particularly so for small firms in the service sector.

First, we show that our results are not specific to family firms nor they are driven by the departure of the founder. Rather, our effects are significantly larger in firms run by professional managers. Second, we investigate whether our results are likely driven by empire building motives, according to which productivity losses are driven by CEOs undertaking inefficient projects, or by the desire of a quiet life, according to which productivity losses are driven by the CEOs putting low effort at work (see e.g. Stein (2003) for a review). We consider several variables often associated to empire building (investments, capex, acquisition activities, cash holdings, leverage, dividends, as well as the investment ratios considered in Ang, Cole and Lin (2000)), and find no significant changes in these variables in relation to our treatment.

Related to quiet life, ideally we would like to measure CEO's effort at work, which is not directly observable. Our data however provide some useful proxies. We observe the number of employment relations the CEO has in other firms and the number of days the CEO has been absent from work. We show both in OLS and in IV regressions that our CEO-owner treatment induces the CEO to take fewer external engagements and fewer days off. These results are suggestive that the quiet life hypothesis is a plausible mechanism behind our treatment effects. When the CEO is also the owner, she exerts more effort at work.

We conclude our analysis by performing a series of robustness checks. We show that our main effects are robust as we employ alternative definitions of treatment and alternative measures of firm productivity; we also consider possible sample selection biases and several specification tests both for our OLS and for our IV estimates.

This paper contributes to the literature on CEO ownership and firm performance. As mentioned, often due to data limitations, this literature has typically focused on listed or very large firms.⁴ On small private firms, Ang et al. (2000)

⁴Morck, Shleifer and Vishny (1988) document an inverted U-shaped relation between CEO ownership and Tobin's Q on Fortune500 firms; a similar relation is found in McConnell and Servaes (1990) on a sample of listed firms. Giroud and Mueller (2011) analyze the effects of governance on stock returns and firm value in more or less competitive industries, Lilienfeld-

define the Jensen and Meckling’s zero agency costs benchmark as a situation in which the CEO is the only owner and show that firms further away from this benchmark are less efficient. Similarly, Bitler et al. (2005) show a positive relation between ownership share and firm performance in a cross-section of U.S. entrepreneurs. Moreover, it has often proven hard to estimate the effects of CEO ownership separately from firm fixed effects, possibly due to limited time-series variation (Himmelberg, Hubbard and Palia (1999) and Zhou (2001)). Our data cover the universe of limited liability firms over a relatively long panel, that allows estimating our effects not only within firms, but within firms with the same CEO or the same largest owner.

Our results are also related to the literature on family firms, and in particular to studies investigating how having a member of the family as CEO affects firm value. Pérez-González (2006), Bennedsen, Nielsen, Pérez-González and Wolfenzon (2007), Bandiera, Lemos, Prat and Sadun (2017), Wang (2019) for example show detrimental effects of family CEOs, while Anderson and Reeb (2003), Villalonga and Amit (2006) and Tsoutsoura (2015) provide a less negative view. Our focus is on the effects of CEO ownership within firm-CEO pairs (as in Bennedsen et al. (2020)), hence controlling for the quality of the CEO and of the firm-CEO match. We also discuss whether our effects are different in firms which are more likely to be run by family members.

More broadly, our work provides distinct and complementary insights to several themes in corporate governance. Relative to studies looking at how firm value is affected by CEO characteristics (e.g. Bertrand and Schoar (2003)) or by the firm-CEO match (Bandiera, Guiso, Prat and Sadun (2015); Bandiera, Prat, Hansen and Sadun (2020)), we focus on the effects of varying the CEO’s ownership share within a given firm-CEO pair. Relative to studies on how ownership structure affects firm value (e.g. Slovin and Sushka (1993); Edmans and Holderness (2017)), our focus is on CEO ownership, keeping other characteristics of the ownership structure fixed. In particular, we abstract from how the firm’s ownership structure affects the degree of effective control over the firm’s operations, which we assume is fully in the CEO’s hands. Lastly, differently from the literature on majority vs. minority shareholders (Shleifer and Vishny (1997)), we focus on the relationship between the CEO and the majority owner.

Toal and Ruenzi (2014) show that firms with larger CEO ownership provide larger stock market returns and suggest this is due to reduced agency conflicts. Fabisik, Fahlenbrach, Stulz and Taillard (2021) expand the sample to about 1,800 firms in the US and show that the relation between CEO ownership and Tobin’s Q is negative.

2 Data

We exploit the Finnish Longitudinal Owner-Employer-Employee database (FLOWN) constructed by Statistics Finland, which we match with balance sheet information from the business register. We obtain a yearly panel from 2006 to 2014 covering the universe of limited companies (*osakeyhtiö*) in the private sector. Our data have three main features. First, we have a rich set of information on firms' characteristics, operations and performance given by their balance sheet. Second, the matched employer-employee structure allows to have information on the employees of the firm, and in particular, as we explain below, to identify its CEO. Third, and most distinctively, we have detailed information on the firms' ownership structure. The Finnish tax authority requires that firms report the identity of the 10 largest shareholders or, if there are more than 10 shareholders, of any shareholder with more than 10% of firm shares. Statistics Finland builds on this information to identify the ultimate individual shareholders of each firm.⁵

We exclude one-man companies and holding companies with no proper business activity (typically, financial firms), and we are left with around 110,000 firms. In our sample, the median firm has 4 employees, 78% of firms are micro firms with less than 10 employees, 18% of firms are small (10-50 employees), 3% are medium (51-250 employees), and 0.8% are large (>250 employees). Manufacturing firms are 36% of the sample (including construction) while the rest are services (including trade).

CEO We are interested in identifying the CEO in each firm, interpreted as the person who has control on the firm's operations. We follow a sequential procedure, similar to the one employed e.g. in Queiró (2016). First, we identify a person as the CEO if he or she is explicitly defined as such among the list of employees. This is the case for 7% of the firms. For the remaining firms, we consider those employees identified as having managerial responsibilities, and say that the CEO is the manager with the highest salary. This identifies an additional 30% of the CEOs. For the remaining firms, we look at whether an active entrepreneur (as classified by the tax administration) appears in the list of employees, in which case

⁵Identifying the ultimate owners is complicated also by the possibility of linkages of firms and business owners via holding companies and enterprise groups. Statistics Finland has implemented a procedure to track down the individual owners behind each firm along the ownership chains. Maliranta and Nurmi (2019) provide a detailed presentation of the data, whose closest counterpart are the Norwegian data used in Berglann, Moen, Røed and Skogstrøm (2011). Given the structure of the data at Statistics Finland, the matching between owners, firms and employees is only possible until 2024.

the person is identified as the CEO.⁶ This is the case for 23% of our CEOs. The remaining 41% of the CEOs are defined as the highest paid worker in the firm. As a validation test, we notice that 86% of the CEOs explicitly defined as such (our first criterion) also have the highest salary in the firm. We also check the robustness of our results with an alternative definition of CEO.⁷

Ownership We observe some ownership information for 92% of the firms in our sample; on average, we observe 82% of the firm ownership. Ownership tends to be rather concentrated: 39.5% of our firms have one shareholder, the median number of shareholders is 2, and 29.9% of the firms have more than 2 shareholders. In firms with more than one shareholder, the average ownership share of the largest shareholder is 41%.

We are interested in comparing situations in which, within a given firm and for plausibly exogenous reasons, the CEO becomes the owner or the owner becomes the CEO, in which case we say that ownership and control are in the same hands, relative to situations in which the two are separated. This requires extending the Jensen-Meckling’s zero agency costs benchmark mentioned above and define the firm’s owner when the firm has multiple shareholders. In our baseline analysis, we focus on the majority owner and accordingly we define our treatment variable as the dummy *CEO Owner*, which equals one when the majority owner is also the CEO.

While our empirical strategy requires defining a dichotomous measure of treatment, we attach no specific value to the 50% threshold in terms of CEO ownership. In fact, as detailed below, changes in our treatment variable are typically associated to large changes in CEO ownership, as opposed to local changes around the 50% threshold. We will show the robustness of our results when considering alternative thresholds.

In our sample, the CEO is also the majority owner in 29% of the firms, and 10.5% of the firms experience a change in the treatment, in 5.6% of the cases the CEO obtains majority, and in the remaining 4.9% the CEO loses majority. As intuitive, these changes are more likely to occur in micro and small firms. We observe large variations in CEO ownership. Conditional on observing a positive

⁶The tax administration identifies an active entrepreneur in a firm if a person owns at least 30% of the shares and receives a significant income from the firm (at least 9,663 euros in 2006).

⁷Specifically, we obtain another register from the Finnish Patent and Registration office (PRH), which provides information on board-members and CEOs of limited liability companies. The coverage is limited to about 70% of our sample. Using this limited sample, we replicate our OLS and IV regressions, and find similar results to our main analysis.

change, the average ownership change is 50%; conditional on a negative change, the average is -43% .⁸ Out of these changes, 26% are associated to a change in the majority owner and so in our treatment *CEO Owner*. Conditional on having a change in the treatment, the average ownership change is 73% for positive changes and -76% for negative changes.

Productivity Our main interest is to investigate how our treatment affects firm’s productivity. In most of our analysis, we define productivity as value added (in real terms) over full time equivalent units of labor.⁹ The measure is constructed directly by Statistics Finland in a way that is comparable across firms and over time. It measures the added value of a worker in the firm without having to estimate the value of capital in the firm, which may be problematic for some firms in our sample (e.g. micro service firms). It does not measure profit and it does not serve as a tax base, so it may be less subject to discretionary accounting practices.¹⁰

We will check the robustness of our results when employing other efficiency and profitability measures (described in more details below). We will also consider productivity measures based on standard TFP estimates, and we will account for possible biases induced by the inability to observe firm level prices.

We winsorize all financial variables, including productivity measures, at the 0.25th and the 99.75th percentiles. Descriptive statistics of our variables appear in Table 1.

3 Baseline Results

3.1 OLS estimates

The first set of results are based on fixed-effects OLS regressions in which we exploit variations in CEO ownership within the same firm with the same CEO. Our basic specification is

$$y_{j,t} = \alpha_j + \beta T_{j,t} + X'_{j,t} \gamma + \mu_t + \varepsilon_{j,t}, \quad (1)$$

⁸In fact, these figures are similar to observed changes in ownership of the largest shareholder (whether or not she is the CEO) for which, conditional on a positive change, the average is 43% and, conditional on a negative change, the average is -38% .

⁹Value added is defined as the value of sales minus the value of purchases, accounting for changes in stocks, other operating incomes and product taxes. An industry specific index based on 2010 prices is used to deflate the nominal value added.

¹⁰We consider productivity in levels, considering its log would give similar results.

where j denotes a firm-CEO pair, $y_{j,t}$ is the productivity of firm-CEO j in year t , α_j and μ_t are respectively firm-CEO and year fixed effects, and $T_{j,t}$ is the dummy *CEO Owner*, which equals one when the CEO owns more than 50% of the firm shares. Our baseline set of controls $X'_{j,t}$ includes industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and characteristics of the firm's board of directors (total number of members, number of members working in the firm, total fraction of shares held by board members).¹¹ We cluster standard errors at the firm level. Our coefficient of interest is β , which measures productivity differences within the same firm-CEO pair in years in which the CEO is the majority owner vs. years in which the two are separated, while controlling for any common time trend and any time-invariant characteristic of the firm, of the CEO, and of the firm-CEO match.

Table 2 reports our estimates. In column 1, we include no control and no fixed effects and observe a negative relation between *CEO Owner* and firm productivity. Once we include our set of controls (column 2) and firm fixed effects (column 3), the relation turns positive. The specification in column 4 corresponds to Equation (1) and includes firm-CEO fixed effects.¹² According to these estimates, *CEO Owner* is associated to around 1,000 euros larger labor productivity, that corresponds to a 1.9% increase relative to the unconditional mean. This effect is large. As comparison, the average productivity growth of private sector Finnish firms in our sample period is 0.7% per year.¹³

In Equation (1), we exploit variations associated to the CEO becoming (or stopping being) the owner. Alternatively, one may fix the firm-owner pair and consider variations associated to the owner becoming (or stopping being) the CEO. For our purposes, both variations should lead to similar insights. Accordingly, we consider the following specification:

$$y_{i,t} = \alpha_i + \beta T_{i,t} + X'_{i,t}\gamma + \mu_t + \varepsilon_{i,t}, \quad (2)$$

in which all terms are as in Equation (1) except that we define a pair i in terms

¹¹Omitting firms that are part of a business group would not change our results.

¹²As we include firm-CEO fixed effects, we do not include controls for CEO's education, age, experience; hence the higher number of observations relative to column 3. Including those controls would not change our results. Moreover, if we restrict the regression in column 4 to the same sample as in column 3, the estimated coefficient is very similar (equal to 1087).

¹³The corresponding figure for EU countries is 0.9% and for the US is 1.13%, see the OECD's website at data.oecd.org.

of a firm and its largest owner. As we have no CEO fixed effects, we also include as control CEO's education, age, tenure and experience. In Equation (2), the coefficient β describes the differences in firm productivity, within a given firm-owner pair, between years in which the owner is also the CEO and years in which the two are separated.

Our results are in column 5 of Table 2, showing that, in the same firm with the same owner, firm productivity is larger when the owner is also the CEO. Specifically, *CEO Owner* is associated to around 785 euros larger labor productivity. This result is important in two respects. First, differently from Equation (1), in Equation (2) we exploit variations on the owner's side, which are less likely to be driven by the CEO's expectations on the future firm productivity.¹⁴ Second, and more generally, the IV approach we develop next considers shocks that may force the CEO to leave, and so induce variations within a given firm-owner pair. These results serve as a useful benchmark for the next IV estimates.

Finally, the estimates in column 5 include cases in which the majority shareholder becomes CEO ($T_{i,t} - T_{i,t-1} = 1$) and cases in which the majority shareholder loses the status of CEO ($T_{i,t} - T_{i,t-1} = -1$). One may ask whether, in absolute value, the effects associated to the two variations are different. In column 6, we check whether the effects of *CEO Owner* are heterogenous with respect to its lagged value $T_{i,t-1}$ and observe that the interaction term $T_{i,t} * T_{i,t-1}$ is not statistically significant. This suggests no significant asymmetries between the two effects, an observation we use again in our IV estimates.¹⁵

3.2 IV estimates

A causal interpretation of our OLS estimates may be challenged for example because changes in ownership and control may be correlated to unobserved pair-specific shocks that may also be correlated to future productivity. Ideally, one would like to exploit purely random changes on whether the main owner is also the CEO. For example, one would like to observe a firm in which the CEO has majority ownership and for exogenous reasons she has to step down as CEO while at the same time keeping her shares, which would induce a separation between ownership and control within the same firm and with the same ownership structure. Symmetrically, one can consider a firm in which the CEO is not the owner,

¹⁴The CEO may decide to leave as he expects future productivity to decrease, but this would go against our results.

¹⁵The same result holds by considering firm-CEO fixed effects, the interaction $T_{j,t} * T_{j,t-1}$ is not significantly different from zero.

she is induced to leave, and she is replaced by the owner, so that ownership and control end up being in the same hands. In the next analysis, we attempt to get as close as possible to such ideal situations. We define pairs in terms of firm and largest owner and exploit shocks induced by worsened health conditions of the CEO and of the CEO spouse.

3.2.1 Instruments

Our first instrument is based on shocks to the CEO’s health. For each CEO, we obtain the amount of health benefits paid out from the Finnish health insurance scheme. The scheme is mandatory, universal, and it compensates the beneficiary for income losses related to health issues. An increase in health benefit is due to worsened health conditions, which can serve as a valid instrument to the extent that health shocks are not driven by expected productivity shocks. The logic of the instrument generalizes, in a somewhat less extreme way, a classic approach of using CEO death as a shock (Johnson et al. (1985), Jenter et al. (2018), Becker and Hvide (2022)) and the approach by Bennedsen et al. (2020), who use CEO hospitalization events in Danish firms.

We use CEO’s health at $t - 1$ as an instrument for changes in the CEO from $t - 1$ to t . The validity of our instrument does *not* rely on excluding direct effects of CEO’s health at t on firm productivity at t , we use past health shocks to induce changes in the CEO. One may also conjecture that past firm performance may affect current CEO’s health. If the CEO changes associated to our health shocks were driven by past firm productivity, however, we would observe a violation of parallel trends, which is not the case. A remaining issue may be that current CEO’s health is directly associated to future firm productivity.

In order to take this possibility into account, one should consider health shocks that induce the CEO to resign but are orthogonal to any dynamics occurring within the firm. One such case is a shock to the CEO spouse’s health. Our data allows us to recover the amount of health benefit paid to the CEO spouse, again by the national health insurance scheme. In fact, to make this test even sharper, we can restrict to CEO spouses who are not working in the firm and so have no direct effect on the firm operations. To our knowledge, this instrument is novel and, in our view, considerably less exposed to the above-mentioned concerns.

In order to appreciate our identification assumption, notice that health shocks induce plausibly exogenous variations in CEO turnover, but they do not necessarily affect her ownership shares. Their validity as instruments requires that their effect

on future firm's productivity is only mediated by the change in the treatment. We then distinguish shocks to productivity that are driven purely by the change of the CEO from those driven by the change in the treatment, i.e. by CEO changes associated to ownership changes, as we explain below.

3.2.2 Specification

In order to implement our IV approach, we consider two specific features of our setting. First, our variable of interest $T_{i,t}$ is a dummy. In fact, we are not instrumenting CEO ownership share *per se*, but rather whether or not the main owner is also the CEO. For this reason, we first estimate a probit regression in which $T_{i,t}$ is regressed over a given instrument $Z_{i,t-1}$ and a set of controls. Then, we use the predicted $\hat{T}_{i,t}$ as an *instrument* in a standard 2SLS regression. As shown in Wooldridge (2010), this allows improving the efficiency of our estimator, which is also robust to possible misspecifications in the probit equation and does not require considering generated regressor issues.¹⁶

A second observation is that the effect of a given instrument $Z_{i,t-1}$ on our treatment $T_{i,t}$ depends on $T_{i,t-1}$. When the CEO is the owner at $t - 1$, the instrument (say, a shock to CEO's health) may induce the CEO to leave and so possibly a negative change to the treatment, from $T_{i,t-1} = 1$ to $T_{i,t} = 0$. When the CEO is not the owner at $t - 1$, the instrument may induce a positive change in the treatment, from $T_{i,t-1} = 0$ to $T_{i,t} = 1$.

Accordingly, our IV estimates are based on the following procedure. First, we estimate the probit regression

$$T_{i,t} = \Phi(\alpha + \beta_1 Z_{i,t-1} + \beta_2 Z_{i,t-1}(1 - T_{i,t-1}) + \beta_3(1 - T_{i,t-1}) + X'_{i,t}\gamma), \quad (3)$$

in which $Z_{i,t-1}$ is one of the above mentioned instrument and in which β_1 measures the effect of the instrument on $T_{i,t}$ when $T_{i,t-1} = 1$. This case is of particular interest, as the instrument induces a plausibly exogenous separation between ownership and control. As mentioned, we then use the predicted $\hat{T}_{i,t}$ as instrument in a 2SLS in which the first stage is a standard OLS.

3.2.3 Results

The results of our IV procedure are reported in Table 3. The bottom part of the table reports the probit estimates of Equation (3), not the first stage of the

¹⁶See Wooldridge (2010) also for a discussion of why the probit regression cannot be used directly as the first stage.

2SLS. The coefficient on $Z_{i,t-1}$ is negative, showing that our instruments have a significant impact on the treatment. If the CEO is the owner at $t - 1$ and, for example, she becomes sick, she is more likely to leave and so induce a negative shock to the treatment. In column 1, the instrument is the amount of health benefits received by the CEO at $t-1$ (in 10,000 euros). In column 2, the instrument is the amount of health benefits received by the CEO spouse.¹⁷ In column 3, we use both CEO health and CEO spouse health as instruments. In column 4 the sample is restricted to cases where the CEO spouse is not an employee of the firm. Results reveal a robust effect. Exploiting plausibly exogenous shocks, we show that firm productivity is significantly larger when ownership and control are in the same hands. Estimated coefficients are similar across specifications, and if anything, larger than the OLS counterpart. IV estimates show that our treatment *CEO Owner* induces an increase of about 1,500 euros in labor productivity, which corresponds to a 2.8% increase.

We notice that our IV estimates are larger than the corresponding OLS. Our preferred interpretation for this difference is in terms of omitted variables. A positive change in *CEO Owner* tends to be associated to a more concentrated ownership, which in turn tends to be negatively correlated to firm productivity. As we show in Section 6, our OLS estimates are reduced by half if we omit the HHI index of ownership concentration from our controls. To the extent that controlling for the HHI index can only partly account for the impact of ownership concentration (as, for example, the measure is noisy, or as the effects are not linear), it is not surprising that our IV estimates are larger than the corresponding OLS. In fact, we show in Section 6 that our IV estimates are instead unchanged as we vary the set of controls.

3.2.4 Exclusion restriction

The validity of our instrument requires that our shocks affect firm productivity at t only through the induced change in the CEO-owner treatment, occurring when the main owner becomes or stops being the CEO. This is not an obvious assumption. For example, the CEO's departure may directly affect firm productivity, say because she has specific skills or knowledge of the firm. As mentioned above, several studies have identified an effect of CEO characteristics on firm's performance (in-

¹⁷In order to keep the same sample throughout columns 2-4, we set health benefit to zero when the CEO has no spouse (that is, we make no distinction between having a spouse with no health benefits and having no spouse). Restricting our sample to CEOs with a spouse would give very similar estimates in terms both of magnitude and of standard errors.

cluding Bertrand and Schoar (2003), Anderson and Reeb (2003), Pérez-González (2006), Villalonga and Amit (2006), Bennedsen et al. (2007), Bandiera et al. (2017)). Moreover, the effect of the CEO’s departure may be particularly large when the departure is unexpected (Smith, Yagan, Zidar and Zwick (2019)). In order to investigate this further, we check whether any change in CEOs induced by our instruments has a similar effect on firm productivity, irrespective of whether or not it is associated to a change in our treatment. If this were the case, the validity of our instrument would be questioned.

We report our results in Table 4, which replicates the structure of Table 3 but looks instead to the effect of *CEO Change*, that is a dummy equal to one if the CEO has changed in any previous period.¹⁸ In column 1, we report OLS estimates and show no significant effect. Compared to the estimate in column 5 of Table 2, this shows that it is not a change in CEO *per se* that drives our effects on firm productivity, but CEO changes associated to changes in our treatment.¹⁹

This is confirmed in IV estimates in columns 2-5. The estimation procedure is the same as in Table 3, except that there is no need to consider the interaction between $Z_{i,t-1}$ and *CEO Change* at $t - 1$ in the probit. In fact, in this case, the effect of our instrument on the probability to have a change of CEO at t need not depend on whether the CEO has changed at $t - 1$. The probit coefficient on $Z_{i,t-1}$ is positive, showing that our instruments indeed significantly increase the probability of having a change in the CEO. Importantly, however, these changes have very different effects on firm productivity from those associated to a change in our CEO-owner treatment.²⁰ We view this as an important finding in support of the validity of our instruments.

4 Small and Large Firms

As mentioned, most of the literature on CEO ownership focuses on samples of very large and/or listed firms. A question is whether the effects identified on those firms are representative of the population and, specifically, whether CEO ownership may have significant effects also in small and medium sized firms.

¹⁸Considering stricter definitions, in which the dummy is equal to one only if the CEO has changed in the previous period or only in the previous two periods, would not qualitatively affect our results.

¹⁹Similarly, one may consider the effect a change in the identity of the majority owner, irrespective of whether or not this is associated to a change in CEO ownership. We observe no significant impact on productivity in this case, suggesting that our effects are related to changes in CEO ownership and not to any change in ownership.

²⁰The difference in the coefficients is statistically different from zero.

We explore this issue in Table 5. In column 1, we fix firm-CEO pairs and check whether the effects of CEO ownership vary with the size of the firm. We interact our treatment indicator with the dummies *Small*, *Medium*, and *Large*, indicating respectively that the firm has 10-50 employees, 51-250 employees, or more than 250 employees. The omitted category are micro firms with less than 10 employees. Estimated effects appear largest for firms with 51-250 employees. In those firms, *CEO Owner* is associated to around 6,700 euros larger labor productivity, as compared to an increase of 893 euros in micro firms and of 1,373 euros in small firms. The interaction between *CEO Owner* and *Large* is not statistically different from zero.

In columns 2-3, we consider as treatment the continuous measure *CEO share*, that is the fraction of shares held by the CEO, instead of *CEO Owner*. In column 2, we observe that also in this specification our effects appear particularly significant in medium-sized firms. We then consider the effect on listed firms. In column 3, we show that the effect of *CEO share* on non-listed firm is positive, while the effect on listed firm is negative. That is, differently than in most firms, larger CEO ownership is associated to lower productivity in listed firms. The result is consistent with Fabisik et al. (2021) who focus on listed firms.²¹ We observe very similar patterns in columns 4-6, where we repeat the same analysis fixing instead the firm-owner pair.

We further explore how our effects vary with the size of the firm using the same IV specifications as in Section 3.2. We interact each instrument with a dummy indicating whether the firm is small, medium or large. Results are reported in Table 6. While some of these estimates are less precise, they confirm the view that CEO ownership matters also outside typical samples of large firms. In fact, the effects appear particularly strong in medium-sized private firms.

This is unlikely to be an artifact of our statistical tests.²² A possible interpretation of our finding is that, relative to small and micro firms, there is larger scope for managerial discretion and it is harder to monitor the CEO in medium-sized firms. At the same time, relative to large public firms, medium-sized firms

²¹It has also been shown that, in listed US firms, the relation between CEO ownership and firm value is inverted U-shaped (Morck et al. (1988), McConnell and Servaes (1990)). Indeed, if we restrict to listed firms, this is the case in our sample as well. However, such non-linearity is not so strong (in fact, the squared term is not significantly different from zero) in the broader sample including non-listed firms.

²²As mentioned, changes in our treatment variable are more likely to occur in small and micro firms, where they also tend to be associated to larger changes in CEO ownership. Hence, from a statistical viewpoint, one may expect our effects to be larger and more precisely estimated in those firms.

face less stringent regulatory constraints and weaker outside markets for corporate control (see Bitler et al. (2005) for a similar argument). While further evidence is needed to shed light on these mechanisms, a key implication of our analysis is that inefficiencies may be particularly severe in those firms that, due to data limitations, are often excluded from corporate governance studies.

5 Interpretation

We further discuss the interpretation of our results by focusing on two questions. First, what is the role of family firms in driving our results; and second, whether agency conflicts can be a way to link CEO ownership and firm productivity in our setting.

5.1 Family Firms and Founder Effect

As mentioned, a large literature on family firms explores how firm value is affected when members of the family or external professionals are appointed as CEOs. Similar issues arise when the founder of the firm, who typically holds specific and possibly essential assets, is replaced. A natural question is whether our results are different in family firms and whether they are driven by the departure of the founder.

While we have no direct way to identify family firms in our sample, we can employ two proxies. We define family firms as those in which the CEO spouse appears in the list of employees or those in which the CEO spouse owns some share in the firm. In columns 1-3 of Table 7, we see that our effects do not vary significantly between family vs. non-family firms.

Similarly, we have no direct way to identify which firms are run by the founder for all firms in our sample. As an approximation, we define founder firms as those which are created during our sample (i.e., after 2006) and in which the CEO has not changed. In column 4 of Table 7, we see that our effects are stronger in firms which are not run by the founder. As shown in column 5, however, we cannot rule out that this differential effect is driven by firm age, i.e., by the fact that our effects are stronger in older firms (those created before 2006). When we restrict to firms created during the sample, the treatment effect is not statistically different in founder firms.

A related question is whether CEOs in our sample are professional managers, and whether the effects of CEO ownership are driven by some dynamics occurring

among family or friends. We proxy firms managed by professionals as those with at least two different CEOs or as those in which the current CEO has worked in at least two different firms during our sample. We observe in column 6 that our effects are significantly larger in firms run by professional managers, supporting the interpretation that these effects are not driven by family relations.

5.2 Empire Building and Quiet Life

We wish to investigate whether agency conflicts can explain how CEO ownership affects firm productivity, and to shed light on which forms of conflicts are more relevant in our setting (see e.g. Stein (2003) for a review). It should be mentioned that the evidence provided here can only be indirect. Our data do not allow to provide direct measures of agency conflicts. In some cases, balance sheet information may be measured with noise; e.g. when estimating the firm’s asset value, which can be particularly problematic for small firms in the service sector.

As agency conflicts, we wish to distinguish in particular between empire building, according to which productivity losses are driven by the manager’s tendency to undertake inefficient projects (Jensen (1986)), and quiet life, according to which productivity losses are driven by the manager’s tendency to put low effort at work (Bertrand and Mullainathan (2003), Giroud and Mueller (2010), Bandiera et al. (2017)).

We first consider variables associated to empire building. Specifically, we test whether *CEO Owner* is associated to changes in investments, assets, capex, acquisition activities, cash holdings, leverage, dividends. We also consider the effects of *CEO Owner* on the investment ratios considered by Ang et al. (2000): financial expenses over turnover; capital investments over turnover; opex over turnover, and net investments over turnover. We report summary statistics of all these variables in Table 1. None of them however appear significantly related to our treatment. The absence of results should be interpreted with caution, due to the above mentioned possibility of noise in the measurement of these variables. It is however suggestive that empire building motives do not appear as a strong driver of our results.

We then consider variables associated to quiet life. While direct measures of CEO’s effort are hard to find, we can observe the number of employment relations the CEO has in other firms (e.g. a second job, board membership, or consultancy). We can also observe the number of days the CEO has been absent from work, typically due to sick leave or for study reasons. In Table 8, we report our estimates

fixing the firm-CEO (columns 1 and 4), fixing the firm-owner (columns 2-3 and 5-6), and the IV as in Table 3 with CEO spouse’s health as instrument, restricting to CEO spouses not working in the firm (columns 5-6). We observe that our treatment induces the CEO to take fewer engagements outside the firm and fewer days of absence from work, which is suggestive of increased effort in the firm.

The result is consistent with Bitler et al. (2005), who find a positive relation between ownership shares and hours worked in a sample of U.S. entrepreneurs and small firms. Bitler et al. (2005) also suggest that hours worked only captures one aspect of increased incentives, and increased ownership may induce many other managerial actions that increase firm value. Many of those actions are difficult to observe, hence conclusions can only be tentative. Yet, these results are suggestive that the quiet life hypothesis is a plausible mechanism behind our treatment effects. When the CEO is also the owner, she exerts more effort at work.

6 Robustness

We perform a series of robustness checks. First, we consider alternative thresholds in our definition of treatment. Second, we consider alternative measures of firm productivity. Third, we consider possible biases related to sample selection. Last, we perform additional specification tests both for our OLS and our IV estimates. For brevity, we present our main results in the text and refer to the Online Appendix for the corresponding tables.

6.1 Treatment Definition

We consider alternative definitions of our treatment. As mentioned, while our main empirical analysis requires a dichotomous treatment, we attach no specific value to the 50% threshold in terms of CEO ownership. In column 1 of Table 9, we consider *CEO 100*, a dummy equal to one if the CEO is the only owner. In column 2, we consider *CEO 0*, a dummy equal to one if the CEO holds any positive fraction of firm’s shares. In column 3, we focus on *CEO Largest*, that is a dummy indicating that the CEO is the largest (though not necessarily the majority) shareholder. In column 4, we consider the continuous variable *CEO shares*. In all these cases, the effect on firm productivity is similar to our main estimates.

In particular, in column 4, we estimate that productivity increases by 1,098

euros following an increase of CEO ownership by 100%. The effect is 8% larger than the coefficient on *CEO Owner* in Table 2, which as mentioned corresponds to an average change in CEO ownership of about 74%. This may suggest some concavity in the effect of CEO ownership, but not strong enough to reject linearity.²³ We explore more explicitly non-linear effects of *CEO Shares* in column 5 and find no significant effect. As shown, these patterns are different in listed firms.

6.2 Productivity Measure

In Table 10, we report a set of robustness checks concerning our productivity measure. In column 1, we consider gross operating surplus (GOS), defined as value added minus personnel costs per unit of labor. In column 2, we consider net profit margin, defined as net profit (value added minus personnel cost, overheads and other costs, interest and taxes) over revenues. In column 3, we consider returns on assets, defined as net income over total assets. These regressions confirm that *CEO Owner* is associated to higher operating efficiency and profitability.

In column 4, we consider a standard estimate of TFP, obtained as the residual of a Cobb-Douglas in which value added is regressed over capital and labor for each 2-digit industry. In column 5, we estimate TFP by adding the firm's market share and fixed effects at the industry-year level. Controlling for industry-specific time trends is a simple way to account for possible biases due to inability to observe firm prices (see Van Beveren (2012) and De Loecker and Goldberg (2014)). In addition, in column 6, we exclude multiproduct firms that may be subject to price shocks in different industries. Again, we observe a positive relation between *CEO Owner* and firm productivity, and our coefficient of interest barely changes across these specifications.²⁴

6.3 Sample Selection

In Table 11, we consider possible biases due to sample selection. Importantly, our sample is not selected in the sense that at each point in time we consider the universe of firms, we do not restrict to survivors. Our fixed effects specifications

²³A similar picture emerges from the estimates in columns 1 and 2. The average change in CEO ownership associated to a positive change in *CEO 100* is 78% and it is -75% for a negative change. The average change in CEO ownership associated to a positive change in *CEO 0* is 63% and it is -62% for a negative change. Out of all changes in CEO ownership, 20% of them are associated to a change in *CEO 100* and 64% are associated to a change in *CEO 0*.

²⁴Similarly, controlling for industry-years fixed effects and market share in our baseline regressions on labor productivity has no effect on our coefficient of interest.

in Equation (1) may also mitigate sample selection biases (Verbeek and Nijman (1992)). As additional checks, we repeat our regressions in Equation (1) on various *selected* samples. In column 1, we restrict the sample to *No Exit* firms, these are firms that do not die in our sample. In column 2, we consider *Persistent* firms, defined as those firms with number of observations above the median, that is equal to 8 (that is, half of our firms are in the sample for 8 years). We repeat the same procedure in terms of firm-CEO pairs, considering in a similar way *No Exit* firm-CEOs (column 3) and *Persistent* firm-CEOs, where the median number of observations for firm-CEOs is 4 (column 4). The estimated impact of *CEO Owner* is similar across the various specifications, and not statistically different from our baseline estimates on the entire population. This limits the concerns that our effects are biased due to sample selection.

6.4 Other specification tests

In columns 5 and 6 of Table 11, we consider specifications in which, instead of firm-CEO fixed effects, we control for lagged values of the dependent variable (one lag in column 5, and three lags in column 6). These specifications are more appropriate if unobserved characteristics are not time invariant within a given firm-CEO pair, but they are instead better captured by time-varying individual-specific past productivity patterns. Estimated effects are still positive and (not significantly) smaller in size.²⁵

In Table 12, we discuss the role of our control variables. We show that, while in general our results change very little by changing the set of controls $X'_{i,t}$ or by considering predetermined values $X'_{i,t-1}$, controlling for ownership concentration has an important effect. In column 1, to ease comparison, we report our baseline specification (as in Table 2, column 4) as well as the coefficients associated to the various control variables. In column 2, we include no controls, and we observe that our treatment effects are smaller (in fact, they are almost half) relative to the baseline estimates. As we show, our key control variable is the HHI index of ownership concentration. In column 3, we include only the HHI index as control, and observe that estimates are very similar to the baseline. If instead we include all our controls except for the HHI index (column 4), estimates are very similar to those without any control. In column 5, we use the lagged values $X'_{i,t-1}$, and observe similar results to those with no controls. This is again driven by ownership

²⁵See e.g. Guryan (2004) for a discussion on how fixed effects and lagged dependent variable specifications provide bounds for the estimated causal effect.

concentration. Once we add the contemporaneous HHI index to the specification (column 6), results are as in the baseline. Positive changes in our treatment are typically associated to an increase in ownership concentration, and ownership concentration is in itself negatively correlated to firm productivity, so omitting it would push our OLS estimates downward.²⁶

6.5 IV specification

As mentioned, our health instruments do not rely on excluding direct effects of CEO's health at t on firm productivity at t . In columns 1-2 of Table 13, we add health at t (that is, $Z_{i,t}$) as control in our 2SLS estimates. In column 1, we see that CEO's health at t has a negative impact on firm productivity at t , while in column 2 the impact of CEO spouse's health is not significant. Irrespective of these effects, our estimated impact of *CEO Owner* is not affected. In our specifications, we fix the firm's largest owner, and any variation to the treatment $T_{i,t}$ is due to changes in the identity of the CEO. In this case, CEO's health at time $t - 1$ is not correlated to health at t , precisely because the CEO is not the same.²⁷

We also consider alternative definitions of our treatment *CEO 100* and *CEO 0*, as defined in Section 3.2. Columns 3-4 present OLS estimates with firm-owner fixed effects, columns 5-6 present IV estimates employing CEO spouse's health as instrument and restricting to CEO spouses not working in the firm. Results are robust and consistent in all these specifications.

Finally, we consider alternative IV specifications. In columns 1-2 of in Table 14, we consider standard 2SLS estimates in which each instrument $Z_{i,t-1}$ is directly used in the first stage. In columns 3-4, we use probit regressions and the predicted $\hat{T}_{i,t}$ as instrument, but differently from Equation (3) we include no interactions with $T_{i,t-1}$. As instruments, we consider CEO's health and CEO spouse's health when the spouse is not employed in the firm. Estimated impacts of *CEO Owner* are still positive and significant, confirming the robustness of our findings.

In Table 15, we replicate the specifications in Table 3 without our set of controls $X'_{i,t}$. We observe that, differently from the OLS estimates reported in Table 12, results are very similar when omitting control variables and in particular when

²⁶See Slovin and Sushka (1993) for causal evidence on the relation between ownership concentration and firm value.

²⁷If this were not the case, we could have for example cases in which the CEO gets sick at $t - 1$, she does not step down, but she rather sells her majority shares. We would observe a change in the treatment, but not a change in the CEO, which may be problematic since for a given CEO health at $t - 1$ is likely to be correlated to health at t and CEO health at t may in turn affect firm productivity at t .

omitting the HHI index of ownership concentration. The result is intuitive since we now keep the identity of the main owner fixed (while in Table 12 we fix the identity of the CEO), and it is also useful to confirm the robustness of our IV estimates to the possibility of omitted variables.

7 Conclusion

We have shown that CEO ownership is an important determinant of firm productivity. This result has been established both in OLS regressions with firm-CEO or firm-owner fixed effects and in IV regressions in which we exploit health shocks to the CEO and to the CEO spouse as a source of exogenous variation in ownership and control. The possibility to exploit ownership data on the universe of limited liability firms has allowed us to estimate the effects of CEO ownership also in samples which have been rarely investigated in the previous literature, showing that our effects are particularly strong in medium-sized private firms, which are usually not the main focus of corporate governance regulation. This finding can also have implications at the macro level, since as mentioned in the introduction those firms have often been considered key for economic growth and job creation.

Additional research is needed to better uncover the mechanisms behind the effects of CEO ownership. An interesting next step would be to investigate more broadly how the firm's ownership structure affects its productivity. Beyond CEO ownership, one can look at the distribution of ownership between large and small shareholders, or between board members, employees and external investors.²⁸ Another interesting direction is to analyze how increased CEO effort improves firm value, the form of this mapping has important implications for agency theory.²⁹ Our analysis is only a first step, we hope it can motivate further investigations and similar data collection efforts in other countries.

NOTE: This table reports summary statistics of all the variables used in our analysis. Minimal and maximal values cannot be reported due to confidentiality. Our productivity variables are measured in euros. CEO ownership variables are dummies, except for CEO Share that is between 0 and 1. In the control variables, Dependent is a dummy. Variables in Placebo, Firm Size and Family Firms are dummies. Instruments are measured in 10,000 euros. Empire Building variables are measured in euros.

Table 2: CEO Ownership and Firm Productivity: OLS Estimates

Dep Variable	Labor Productivity					
	(1)	(2)	(3)	(4)	(5)	(6)
CEO Owner	-3,556 (-33.75)***	827.80 (7.22)***	861.95 (5.86)***	1,010 (3.34)***	784.18 (4.87)***	954.68 (3.93)***
CEO Owner * Lagged CEO Owner						-309.80 (-1.03)
Lagged CEO Owner						287.92 (1.30)
Controls	No	Yes	Yes	Yes	Yes	
Fixed Effects	No	No	Firm	Firm-CEO	Firm-Owner	
Number of Obs	566,266	555,406	555,406	566,260	555,406	390,410
Number of Groups			109,502	214,077	145,578	96,374
R-squared	0.001	0.173	0.015	0.013	0.015	0.019

NOTE: This table reports the results of OLS regressions. The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. Lagged CEO Owner is the value of CEO Owner in the previous year. In column 3, regressions include firm and year fixed effects. In column 4, regressions include firm-CEO and year fixed effects. In columns 5-6, regressions include firm-owner and year fixed effects. In columns 2-6, controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. In addition, in column 3,5,6 controls include CEO's education, age, years of experience within the firm and in total. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 3: CEO Ownership and Firm Productivity: IV Estimates

Dep Variable	Labor Productivity			
	(1)	(2)	(3)	(4)
CEO Owner	1,519 (2.52)**	1,508 (2.50)**	1,589 (2.36)**	1,554 (2.09)**

Z(t-1)*(1-T(t-1))	0.674 (9.17)***	-0.050 (-0.65)	0.674 (9.17)***	0.063 (0.67)
Z'(t-1)			-0.134 (-2.40)**	
Z'(t-1)*(1-T(t-1))			-0.050 (-0.65)	
Instrument	CEO Health	Spouse Health	CEO Health Spouse Health	Spouse Health (not working)
Fixed Effects	Firm-Owner			
Number of Obs	367,895	367,895	367,895	289,991
Number of Groups	74,640	74,640	74,640	63,001
R-squared	0.02	0.02	0.01	0.02

NOTE: This table reports results of Probit and IV regressions. The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. The bottom panel report probit regressions of equation (3). In column 1, the instrument is the amount of health benefits received by the CEO in the previous period (in 10,000 euros). In column 2, the instrument is the amount of health benefits received by the CEO spouse in the previous period (in 10,000 euros). In column 3, both the amount of health benefits received by the CEO and by the CEO spouse are used as instruments. In column 4, the instrument is the amount of health benefits received by the CEO spouse and the sample is restricted to cases where the CEO spouse is not an employee of the firm. All regressions include firm-owner and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 4: Placebo Tests

Dep Variable	Labor Productivity			
	(1)	(2)	(3)	(4)
CEO Change	188.04 (1.22)	-2,836 (-0.58)	1,587 (0.33)	-2,848 (-0.55)
	Probit			
Z(t-1)		0.155 (5.75)***	0.103 (4.27)***	0.065 (2.24)**
Instrument		CEO Health	Spouse Health (not working)	
Fixed Effects		Firm-Owner		
Number of Obs	555,406	367,905	367,905	290,001
Number of Groups	145,578	74,641	74,641	63,002
R-squared	0.01	0.02	0.02	0.02

NOTE: This table reports results of OLS regressions (column 1) and of Probit and IV regressions (columns 2-4). The dependent variable is labor productivity. CEO Change is a dummy equal to one if the CEO has changed in any previous period. The bottom panel of columns 2-4 report probit regressions as in equation (4) without interactions with T(t-1). In column 2, the instrument is the amount of health benefits received by the CEO in the previous period (in 10,000 euros). In columns 3-4, the instrument is the amount of health benefits received by the CEO spouse in the previous period (in 10,000 euros). In column 4, the sample is restricted to cases where the CEO spouse is not an employee of the firm. All regressions include firm-owner and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 5: CEO Ownership in Small and Large Firms (OLS)

Dep Variable	Labor Productivity					
	(1)	(2)	(3)	(4)	(5)	(6)
Treat	892.87 (2.11)**	649.08 (1.62)	1,005 (2.63)***	693.25 (3.55)***	723.00 (3.18)***	952.46 (4.48)***
Treat*Small	1,373 (2.54)***	1,962 (2.98)***		573.69 (1.56)	1,277 (2.79)***	
Treat*Medium	6,696 (3.28)***	5,701 (2.35)**		2,724 (2.02)**	2,178 (1.38)	
Treat*Large	1,723 (0.25)	8,265 (0.54)		3,113 (0.79)	4,489 (0.47)	
Treat*Listed			-197,202 (-1.70)*			-29,538 (-0.48)

Number of Obs	313,789	313,789	313,789	390,410	390,410	390,410
Number of Groups	112,875	112,875	112,875	96,374	96,374	96,374
R-squared	0.019	0.019	0.018	0.019	0.019	0.019

NOTE: This table reports the results of OLS regressions. The dependent variable is labor productivity. In columns 1 and 4, Treat is CEO Owner, that is a dummy equal to one if the CEO has majority ownership in the firm. In columns 2-3 and 5-6, Treat is CEO Shares, that is the fraction of CEO ownership in the firm. Small is a dummy equal to one if the firm has 10-50 employees, Medium is a dummy equal to one if the firm has 51-250 employees, Large is a dummy equal to one if the firm has more than 250 employees. Listed is a dummy equal to one if the firm is listed. In columns 1-3, we include firm-CEO and year fixed effects; In columns 4-6, we include firm-owner and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 6: CEO Ownership in Small and Large Firms (IV)

Dep Variable	Labor Productivity			
	(1)	(2)	(3)	(4)
CEO Owner	812.05 (1.27)	620.41 (0.82)	852.51 (1.24)	1,336.48 (1.17)

R-squared	0.019	0.019	0.019	0.019	0.019	0.019

NOTE: This table reports the results of OLS regressions. The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. Spouse Works is a dummy equal to one if the CEO spouse is an employee in the firm. Spouse Owns is a dummy equal to one if the CEO spouse holds some share in the firm. Family is a dummy equal to one if the CEO spouse is an employee or holds some share in the firm. Founder is a dummy equal to one if the firm was created during our sample and it has not changed the CEO. In column 5, the sample is restricted to firms created during our sample. Professional CEO is a dummy equal to one if the firm has at least two different CEOs or if the current CEO has worked in at least two different firms during our sample. All regressions include firm-CEO and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 8: Quiet Life

NOTE: This table reports the results of OLS regressions. The dependent variable is labor productivity. CEO 100 is a dummy equal to one if the CEO has 100% ownership in the firm. CEO 0 is a dummy equal to one if the CEO has some ownership in the firm. CEO Largest is a dummy equal to one if the CEO is the largest shareholder in the firm. CEO Share is the fraction of CEO ownership in the firm. All regressions include firm-CEO and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 10: Robustness (OLS): Productivity Measures

Dep Variable	GOS	Profit	ROA	TFP	TFP2	
	(1)	(2)	(3)	(4)	(5)	(6)
CEO Owner	1,020 (4.16)***	0.006 (1.88)**	1.274 (2.76)***	0.014 (2.79)***	0.015 (2.87)***	0.018 (3.38)***

R-squared	0.017	0.009	0.024	0.007	0.007	0.007

NOTE: This table reports the results of OLS regressions. In column 1, the dependent variable is Gross Operating Surplus. In column 2, the dependent variable is net profit margin. In column 3, the dependent variable is Returns on Assets. In column 4, the dependent variable is TFP, obtained as the residual of a Cobb-Douglas in which value added is regressed over capital and labor for each 2 digit industry. In column 5, TFP is estimated by adding firm's market share and fixed effects for industry-years. In column 6, TFP is estimated as in column 5 but multiproduct firms are excluded. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. All regressions include firm-CEO and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 11: Robustness (OLS): Sample Selection and Specification Tests

Dep Variable	Labor Productivity					
	(1)	(2)	(3)	(4)	(5)	(6)

NOTE: This table reports the results of OLS regressions. The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. In column 1, we restrict the sample to firms that do not die in our sample. In column 2, we restrict the sample to firms with number of observations above the median (equal to 9). In column 3, we restrict the sample to firm-CEO pairs that do not die in our sample. In column 4, we restrict the sample to firm-CEO pairs with number of observations above the median (equal to 4). In columns 5 and 6, LP(t-1)-LP(t-3) are lagged values of labor productivity with 1-3 lags. Regressions in columns 1-4 include firm-CEO and year fixed effects, regressions in column 5-6 include year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

NOTE: This table reports the results of OLS regressions. The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. In columns 1 and 4, we include contemporaneous values of controls (firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar) and board characteristics). In columns 5-6, we include one period lagged values of these controls. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 13: Robustness (IV): Contemporaneous Health and Treatment Definition

NOTE: This table reports results of OLS regressions (columns 3-4) and of Probit and IV regressions (columns 1-2 and 5-6). The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. CEO 100 is a dummy equal to one if the CEO has 100% ownership in the firm. CEO 0 is a dummy equal to one if the CEO has some ownership in the firm. The bottom panel of columns 1-2 and 5-6 report probit regressions of equation (3). In column 1, the instrument is the amount of health benefits received by the CEO in the previous period (in 10,000 euros). In columns 2,5,6, the instrument is the amount of health benefits received by the CEO spouse in the previous period (in 10,000 euros) and the sample is restricted to cases where the CEO spouse is not an employee of the firm. In columns 1 and 2, Z(t) correspond to the amount of health benefits received the current period. All regressions include firm-owner and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 14: Robustness (IV): Alternative Specifications

Dep Variable	Labor Productivity

R-squared	0.02	0.02	0.02	0.02

NOTE: This table reports results of IV and Probit regressions. The dependent variable is labor productivity. CEO Owner is a dummy equal to one if the CEO has majority ownership in the firm. The bottom panel of columns 1-2 reports first stage OLS regressions. The bottom panel of columns 3-4 reports probit regressions as in equation (3) without interactions with T(t-1). In columns 1 and 3, the instrument is the amount of health benefits received by the CEO in the previous period (in 10,000 euros). In columns 2 and 4, the instrument is the amount of health benefits received by the CEO spouse in the previous period (in 10,000 euros) and the sample is restricted to cases where the CEO spouse is not an employee of the firm. All regressions include firm-owner and year fixed effects. Controls include industry fixed effect (2 digits), firm's age, leverage, a dummy indicating if the firm is part of a business group, the number of workers by level of education and occupation (white vs. blue collar), the HHI index of ownership concentration and board characteristics. Standard errors are clustered by firm, t-statistics are in parentheses. *, ** and *** denotes significance at 10%, 5% and 1% level, respectively.

Table 15: Robustness (IV): Control Variables
